Built-In-Self-Test (BIST) for Embedded Systems

1. Introduction

BIST is a design-for-testability technique that places the testing functions physically with the circuit under test (CUT), as illustrated in Figure 40.1 [1]. The basic BIST architecture requires the addition of three hardware blocks to a digital circuit: a test pattern generator, a response analyzer, and a test controller. The test pattern generator generates the test patterns for the CUT. Examples of pattern generators are a BCD to serial pattern generator, a counter, and a linear feedback shift register (LFSR). A typical response analyzer is a comparator with stored responses or an LFSR used as a signature analyzer. It compares and analyzes the test responses to determine correctness of the CUT. A test control block is necessary to activate the test and analyze the responses. However, in general, several test-related functions can be executed through a test controller circuit.

Fig. 40.1 A Typical BIST Architecture

As shown in Figure 40.1, the wires from primary inputs (PIs) to MUX and wires from circuit output to primary outputs (POs) cannot be tested by BIST. In normal operation, the CUT receives its inputs from other modules and performs the functions for which it was designed. During test mode, a test pattern generator circuit applies a sequence of test patterns to the CUT,

and the test responses are evaluated by a output response comparator. In the most common type of BIST, test responses are compared in output response comparator to form faulty signatures. The response signatures are compared with reference golden signatures generated in stored memory, and the error signal indicates whether chip is good or faulty. Four primary parameters must be considered in developing a BIST methodology for embedded systems, those compared with the design parameters for on-line testing techniques discussed in earlier chapter [2].

- **Fault coverage:** This is the fraction of faults of interest that can be exposed by the test patterns produced by pattern generator and detected by output response monitor. In presence of input bit stream errors there is a chance that the compared signatures matches the golden signatures, and the circuit is reported as fault free. This undesirable property is called masking or aliasing.
- **Test set size:** This is the number of test patterns produced by the test generator, and is closely linked to fault coverage; generally, large test sets imply high fault coverage.
- **Hardware overhead:** The extra hardware required for BIST is considered to be overhead. In most embedded systems, high hardware overhead is not acceptable.
- **Performance overhead:** This refers to the impact of BIST hardware on normal circuit performance such as its worst-case (critical) path delays. Overhead of this type is sometimes more important than hardware overhead.

Issues for BIST

- **Area Overhead:** Additional active area due to test controller, pattern generator, response evaluator and testing of BIST hardware.
- **Pin Overhead:** At least 1 additional pin is needed to activate BIST operation, input MUX, add extra pin overhead.
- **Performance overhead:** Extra path delays are added due to BIST.
- **Yield loss increases:** due to increased chip area.
- **Design effort and time increases:** due to design BIST.
- **The BIST hardware complexity increases:** when the BIST hardware is made versatile.

Benefits of BIST

- It reduces testing and maintenance cost, as it requires simpler and less expensive ATE.
- BIST significantly reduces cost of automatic test pattern generation (ATPG).
- It reduces storage and maintenance of test patterns.
- It can test many units in parallel.
- It makes shorter test application times.
- It can test an functional systems speed.

BIST can be used for non-concurrent, on-line testing of the logic and memory parts of a system [2]. It can readily be configured for event-triggered testing, in which case, the BIST control can be tied to the system reset so that testing occurs during system start-up or shutdown. BIST can also be designed for periodic testing with low fault latency. This requires incorporating a testing process into the CUT that generates the detection of all target faults within a fixed time.

On-line BIST is usually implemented with the main goals of complete fault coverage and low fault latency. Hence, the test generator (TGO) and response monitor (RMO) are generally designed

Fault-Tolerance Techniques for SRAM-Based FPGAs Fernanda Lima Kastensmidt, Ricardo Reis, 2007-02-01 Fault

tolerance in integrated circuits is not an exclusive concern regarding space designers or highly reliable application engineers. Rather, designers of next generation products must cope with reduced margin noises due to technological advances. The continuous evolution of the fabrication technology process of semiconductor components in terms of transistor geometry shrinking, power supply speed and logic density has significantly reduced the reliability of very deep submicron integrated circuits in face of the various internal and external sources of noise. The very popular Field Programmable Gate Arrays (FPGAs) customizable by SRAM cells are a consequence of the integrated circuit evolution with millions of memory cells to implement the logic embedded memories routing and more recently with embedded microprocessors cores. These re-programmable systems on chip platforms must be fault tolerant to cope with present days requirements. This book discusses fault tolerance techniques for SRAM based Field Programmable Gate Arrays (FPGAs). It starts by showing the model of the problem and the upset effects in the programmable architecture. In the sequence it shows the main fault tolerance techniques used nowadays to protect integrated circuits against errors. A large set of methods for designing fault tolerance systems in SRAM based FPGAs is described. Some presented techniques are based on developing a new fault tolerant architecture with new robustness FPGA elements. Other techniques are based on protecting the high level hardware description before the synthesis in the FPGA. The reader has the flexibility of choosing the most suitable fault tolerance technique for its project and to compare a set of fault tolerant techniques for programmable logic applications.

[The Core Test Wrapper Handbook](#)
Francisco da Silva, Teresa McLaurin, Tom Waayers, 2006-09-15

In the early to mid 1990s while working at what was then Motorola Semiconductor business changes forced my multi hundred dollar microprocessor to become a tens of dollars embedded core. I ran into first hand the problem of trying to deliver what used to be a whole chip with something on the order of over 400 interconnect signals to a design team that was going to stuff it into a package with less than 220 signal pins and surround it with other logic. I also ran into the problem of delivering microprocessor specification verification. A microprocessor is not just about the functions and instructions included with the instruction set but also the MIPs rating at some given frequency. I faced two dilemmas: one I could not deliver functional vectors without significant development of off core logic to deal with the reduced chip I/O map and everybody's I/O map was going to be a little different and two the JTAG 1149.1 boundary scan ring that was around my core when it was a chip was going to be woefully inadequate since it did not support speed signal application and capture and independent use separate from my core. I considered the problem at length and came up with my own solution that was predominantly a separate non JTAG scan test wrapper that supported at speed application of launch/capture cycles using the system clock. But my problems weren't over at that point either.
