Parathyroid adenomas (PAs) causing primary hyperparathyroidism (PHPT) are histologically heterogeneous yet have been historically viewed as largely monotypic entities arising from clonal expansion of a single transformed progenitor. Using flow cytometric analysis of resected adenomatous parathyroid glands, we have isolated and characterized chief cells, oxyphil cells, and tumor-infiltrating lymphocytes. The parathyroid chief and oxyphil cells produce parathyroid hormone (PTH), express the calcium-sensing receptor (CASR), and mobilize intracellular calcium in response to CASR activation. Parathyroid tumor-infiltrating lymphocytes are T cells by immunophenotyping. Under normocalcemic conditions, oxyphil cells produce ~50% more PTH than do chief cells, yet display significantly greater PTH suppression and calcium flux response to elevated calcium. In contrast, CASR expression and localization are equivalent in the respective parathyroid cell populations. Analysis of tumor clonality using X-linked inactivation assays in a patient-matched series of intact tumors, preoperatively isolated oxyphil and chief cells, and laser-captured microdissected PA specimens demonstrate polyclonality in 5 of 14 cases. These data demonstrate the presence of functionally distinct oxyphil and chief cells within parathyroid primary adenomas and provide evidence that primary PA can arise by both clonal and polyclonal mechanisms. The clonal differences, biochemical activity, and relative abundance of these parathyroid adenoma subpopulations likely reflect distinct mechanisms of disease in PHPT.

tumor heterogeneity | endocrine neoplasia

The parathyroid glands maintain serum calcium concentration within a narrow physiological range through regulated synthesis and secretion of parathyroid hormone (PTH) (1). Parathyroid neoplasia results in inappropriate secretion of PTH by one or more glands, leading to hypercalcemia and the disease primary hyperparathyroidism (PHPT) (2). To date, research in the field has focused on histologic and molecular profiling of parathyroid tumors and the investigation of calcium sensing in dispersed cells from parathyroid tumors and normal bovine parathyroid glands. Few studies have characterized the individual cellular constituents of human parathyroid tumors, and no publications have reported live-cell functional evaluation of the different cellular subtypes observed in parathyroid tumors.

Parathyroid adenomas, the most common cause of PHPT, are considered clonal proliferations of a transformed parathyroid cell that has acquired proliferative or survival advantage due to one of several genetic abnormalities including the PRAD1 translocation or mutations in the genes encoding *menin*, *P53*, and *P27* (3–7). Regardless of type, most authors consider parathyroid tumors clonal (8, 9) although intratumoral heterogeneity has been observed and polyclonality of microdissected parathyroid adenomas has been reported (10, 11).

Although most data support mutation-driven clonal expansion of parathyroid tumors, an alternative model for the origin of parathyroid tumors is that abnormal calcium sensing by para-

thyroid cells leads to abnormal secretion of PTH initially, followed by proliferation of parathyroid cells in response to chronic demand for increased PTH (12, 13). An abnormal calcium–PTH set point has been well-described in aggregate dispersed cells from parathyroid adenomas, and most reports attribute the impaired set point in these cells to decreased expression of the calcium-sensing receptor (CASR) (14, 15) or more recently to altered expression of downstream molecules linked to CASR signaling, including RhoGEF and RGS5 (16, 17). In contrast to clonal expansion following genomic tumor-initiating events, attenuated calcium responsiveness could be expected to drive polyclonal proliferation in the parathyroid gland.

To investigate the composition of parathyroid tumors, we sought to characterize a series of parathyroid adenomas at the cellular and functional level. In this study, we report the isolation and characterization of chief cells, oxyphil cells, and lymphocytes present in parathyroid adenomas and histologically normal parathyroid glands from patients with PHPT. Our results show that parathyroid adenomas removed from patients with PHPT are composed of functionally and genetically distinct oxyphil and chief cells and have varying amounts of infiltrating lymphocytes. The chief and oxyphil cells within parathyroid adenomas have differing ability to respond to changes in ambient calcium and produce PTH although CASR expression is comparable between these parathyroid cell subtypes. Further, we show that a significant proportion of PHPT patients have polyclonal tumors. The relative abundance, functional behavior, and clonal origin of

## Significance

Parathyroid adenomas, the main cause of primary hyperparathyroidism (PHPT), are thought to result from clonal expansion of tumor cells and to be insensitive to normal calcium feedback due to the loss of the calcium-sensing receptor (CASR). Utilizing flow cytometric analysis to isolate and individually study oxyphil cells, chief cells, and lymphocytes from resected parathyroid tumors and glands, we now report previously unrecognized heterogeneity in these tissues with respect to calcium responsiveness, CASR expression, and clonal origin of parathyroid tumors. Such heterogeneity of parathyroid adenomas likely reflects the complex etiopathogenesis and clinical heterogeneity of PHPT.
